ExtrapoLATE-ing: External Validity and Overidentification in the LATE framework

Josh Angrist Iván Fernández-Val MIT BU

May 2011

Instrumental Variables and External Validity

- IV identifies a Local Average Treatment Effect (LATE): the causal effect of an instrument-induced shift in treatment
- Each LATE is tied to the instrument that generates it
- Is this surprising or troubling? Could it be otherwise?
 - Draft lottery instruments tell us the effect of being drafted, not necessarily volunteering
 - Compulsory schooling instruments reflect the effect of high school graduation, not an MBA
- The LATE framework highlights questions of external validity
 - Can one instrument identify the average effect induced by another source of variation?
 - Can we go from average effects on compliers to average effects on the entire treated population or an unconditional effect?
- The answer to these questions is usually "no," at least, not without additional assumptions ...

Framework

- Potential outcomes, ${\rm Y}_0$ and ${\rm Y}_1,$ describe what happens under alternative assignments of treatment, ${\rm D}$
- The observed outcome, Y, is

$$\mathbf{Y} = \mathbf{Y}_0 + (\mathbf{Y}_1 - \mathbf{Y}_0)\mathbf{D}$$

- Potential assignments are D^z₁ when the instrument, Z, is switched on and D^z₀ when Z is switched off
- Observed treatment status is

$$\mathbf{D} = \mathbf{D}_0^z + (\mathbf{D}_1^z - \mathbf{D}_0^z)\mathbf{Z}$$

- Note the instrument-specific notation for potential assignments
- \bullet Covariates are denoted by the vector \boldsymbol{x}

LATE Theorem: Imbens and Angrist (1994)

Assume:

(a) Independence and Exclusion:
$$(Y_1, Y_0, D_1^z, D_0^z) \amalg Z$$

(b) First-stage: $\mathbb{E}[D_1^z - D_0^z] \neq 0$ and $0 < \mathbb{P}[Z = 1] < 1$

(c) Monotonicity: $D_1^z \ge D_0^z$ a.s., or vice versa

Then,

$$\frac{\mathbb{E}[\mathbf{Y} \mid \mathbf{z} = 1] - \mathbb{E}[\mathbf{Y} \mid \mathbf{z} = 0]}{\mathbb{E}[\mathbf{D} \mid \mathbf{z} = 1] - \mathbb{E}[\mathbf{D} \mid \mathbf{z} = 0]} = \mathbb{E}[\mathbf{Y}_1 - \mathbf{Y}_0 \mid \mathbf{D}_1^z > \mathbf{D}_0^z] := \Delta^z$$

- IV using z as an instrument for the effect of ${\rm D}$ on ${\rm Y}$ with no covariates is the (1940) Wald estimator
- Three instrument-defined subgroups:

(a) Z-compliers;
$$D_1^z = 1$$
 and $D_0^z = 0$
(b) Z-always-takers; $D_1^z = D_0^z = 1$
(c) Z-never-takers; $D_1^z = D_0^z = 0$

• LATE using \boldsymbol{z} is the effect of treatment on $\boldsymbol{z}\text{-compliers}$

The Covariate Approach to External Validity

- LATE is the average causal effect on compliers: we can't *name* them but we can still get to know them
- The distribution of complier characteristics is identified and easily estimated (Abadie 2003; Angrist and Pischke, 2009)
- We assume here that differences in complier characteristics are what makes a given LATE estimate special; this is *Conditional Effect Ignorability* (CEI)
 - CEI can be used to explain the difference in LATE across instruments
 - CEI can be used to explain the difference between LATE and ATE or effects on the treated and nontreated
- CEI can be used for estimation
 - Covariate-specific LATEs can be weighted to produce ATE, effects on the treated, or hypothetical LATE with a different complier population

Example: Childbearing Effects on Labor Supply

- The potential for omitted variable bias in the relationship between fertility and labor supply seems clear
 - Mothers with weak labor force attachment or low earnings potential may be more likely to have children
- Angrist and Evans (1998) use two IVs to solve this problem
 - **1** *Twins*: a dummy for a multiple second birth in a sample of mothers with at least two children
 - 2 Samesex: a dummy for same-sex sibling pairs (American parents want a diversified sibling-sex portfolio)
- Wald estimates are reported in Table 1
- *Twins* and *samesex* IV estimates both suggest that the birth of a third child has a substantial effect on weeks worked and employment
- But *Twins* IV estimates are about half as large as those using *samesex* . . . Can this be explained by differences in complier characteristics?

Complier Characteristics

- How do twins and samesex compliers differ?
- $\bullet\,$ Suppose x is an indicator for college graduates. Then,

$$\frac{\mathbb{P}[\mathrm{x}=1\mid \mathrm{D}_1^z > \mathrm{D}_0^z]}{\mathbb{P}[\mathrm{x}=1]} = \frac{\mathbb{E}[\mathrm{D}\mid \mathrm{z}=1, \mathrm{x}=1] - \mathbb{E}[\mathrm{D}\mid \mathrm{z}=0, \mathrm{x}=1]}{\mathbb{E}[\mathrm{D}\mid \mathrm{z}=1] - \mathbb{E}[\mathrm{D}\mid \mathrm{z}=0]}$$

- Relative likelihood a complier is college grad is given by the ratio of the first stage for college graduates to the overall first stage
- For general x, the mean of covariates for compliers can be obtained using Abadie's (2003) kappa-weighting scheme:

$$\mathbb{E}[\mathbf{x} \mid \mathbf{D}_1 > \mathbf{D}_0] = \frac{\mathbb{E}[\kappa(\mathbf{z})\mathbf{x}]}{\mathbb{E}[\kappa(\mathbf{z})]},$$

where

$$\kappa(\mathbf{z}) = 1 - \frac{\mathbf{D}(1-\mathbf{z})}{1 - \mathbb{P}[\mathbf{z}=1]} - \frac{(1-\mathbf{D})\mathbf{z}}{\mathbb{P}[\mathbf{z}=1]}$$

Complier Characteristics (cont.)

- Panel A of Table 2 reports compliers' characteristics ratios for schooling and age dummies; Kappa weighting is illustrated in Panel B
- Both panels show that *twins* compliers are:
 - More likely than samesex compliers to have a young second-born (women w/very young second borns can only have a 3rd via multiples)
 - More educated than *samesex* compliers
- Samesex compliers have/are:
 - Older than average second-borns
 - Less educated than average (less likely to be college graduates)
- Age of second born and education are important mediators of the causal effects of childbearing
 - Women with a young second-born at home should be less affected by the birth of a third child
 - Educated women adjust labor supply less when family size increases (they pay for child care)

Conditional Effect Ignorability

Covariates play two roles in our setup:

- 1 Supporting identification (conditional ignorability of IV)
- 2 A possible basis for extrapolation

Assumption (Conditional LATE assumptions)

(a) Independence and Exclusion: $(Y_1, Y_0, D_1^z, D_0^z) \amalg z \mid x \text{ a.s.}$ (b) First stage: $\mathbb{E}[D_1^z - D_0^z \mid x] \neq 0$ and $0 < \mathbb{P}[z = 1 \mid x] < 1$ a.s. (c) Monotonicity: $\mathbb{P}[D_1^z \ge D_0^z \mid x] = 1$ or $\mathbb{P}[D_1^z \le D_0^z \mid x] = 1$ a.s.

Assumption (Conditional Effect Ignorability for an instrument z)

$$\mathbb{E}[\mathbf{y}_1-\mathbf{y}_0\mid \mathbf{D}_1^z,\mathbf{D}_0^z,\mathbf{X}]=\mathbb{E}[\mathbf{y}_1-\mathbf{y}_0|\mathbf{X}] \ \text{ a.s.}$$

• A sufficient condition for CEI is

$$\mathbf{Y}_1 = \mathbf{Y}_0 + \boldsymbol{g}(\mathbf{X}) + \boldsymbol{\nu},$$

where ν is mean-independent of (D_1^z, D_0^z) conditional on X

LATE-Reweight Theorem

Covariate-specific LATE using z,

$$\Delta^{z}(x) := \mathbb{E}[Y_{1} - Y_{0} \mid D_{1}^{z} > D_{0}^{z}, X = x]$$

$$(1)$$

Theorem (Reweighting LATE)

Let z be an instrument that satisfies CEI and cond. LATE identification and let $s^z = s(D_0^z, D_1^z, z)$ be an indicator for any subpopulation defined by z. For example, for z-compliers $s^z = D_1^z - D_0^z$, for the treated $s^z = (1-z)D_0^z + zD_1^z = D$, and for the population $s^z = 1$. Assuming $\mathbb{E}[|Y|] < \infty$,

$$\mathbb{E}[\mathbf{Y}_1 - \mathbf{Y}_0 \mid \mathbf{S}^z = 1] = \mathbb{E}[\Delta^z(\mathbf{X}) \mid \mathbf{S}^z = 1] = \int \Delta^z(x) \omega_{\mathbf{S}}^z(x) dF_{\mathbf{X}}(x),$$

where

$$\omega_{s}^{z}(x) = \mathbb{P}[s^{z} = 1 \mid x = x] / \mathbb{P}[s^{z} = 1]$$

and $\int \omega_{\rm S}^{z}(x) dF_{\rm X}(x) = 1$.

Reweighting LATE

• This result allows us to construct Δ^z , TOT, TNT, ATE using weights

$$\omega_{\Delta}^{z}(x) = \frac{\mathbb{E}[\mathbf{D} \mid \mathbf{z} = 1, \mathbf{x} = x] - \mathbb{E}[\mathbf{D} \mid \mathbf{z} = 0, \mathbf{x} = x]}{\mathbb{E}[\mathbf{D} \mid \mathbf{z} = 1] - \mathbb{E}[\mathbf{D} \mid \mathbf{z} = 0]}$$

for z-compliers;

$$\omega_{TOT}^{z}(x) = \mathbb{E}[\mathbf{D} \mid \mathbf{X} = x] / \mathbb{E}[\mathbf{D}]$$

for the treated;

$$\omega_{TNT}^{z}(x) = \mathbb{E}[1 - D \mid X = x] / \mathbb{E}[1 - D]$$

for the non-treated; and

$$\omega_{ATE}^{z}(x) = 1$$

for the population

From One LATE to Another

• Let $\Delta^w(x)$ be defined as in (1) using the instrument w. Then,

$$\Delta^{z} - \Delta^{w} = \int [\Delta^{z}(x) - \Delta^{w}(x)] \omega_{\Delta}^{z}(x) dF_{x}(x) + \int \Delta^{w}(x) [\omega_{\Delta}^{z}(x) - \omega_{\Delta}^{w}(x)] dF_{x}(x)$$

• If \boldsymbol{z} and \boldsymbol{w} satisfy CEI,

$$\Delta^w(\mathbf{X}) = \Delta^z(\mathbf{X}) \text{ a.s.}$$

We can then reweight to go from one LATE to another:

Theorem (OLTA)

Let $s^w = s(D_0^w, D_1^w, W)$ be an indicator for any subpopulation defined by instrument W. If $\mathbb{E}[|Y|] < \infty$,

$$\mathbb{E}[\mathbf{Y}_1 - \mathbf{Y}_0 \mid \mathbf{S}^w = 1] = \int \Delta^w(x) \omega^w_{\mathbf{S}}(x) dF_{\mathbf{X}}(x) = \int \Delta^z(x) \omega^w_{\mathbf{S}}(x) dF_{\mathbf{X}}(x)$$

Compatible Average Treatment Effects (CATE)

- In practice, CEI may be satisfied only for some covariate values
- Estimates for a population defined by *compatible* covariate-specific effects may have high predictive value . . . for the compatible
- CATE is

$$\Delta_{c}^{z,w} = \int \Delta^{z}(x) dF_{X}(x \mid \Delta^{z}(x) = \Delta^{w}(x))$$

- We can use covariate-specific overid tests to find the compatible subpopulation
- If CEI holds for z and w for all values of x, CATE is ATE; Otherwise, CATE is ATE for the *compatible subpopulation*
- Rationales for CATE
 - We'd like to report estimates for the largest and most representative subpopulation possible; that might be TOT|CATE
 - At compatible covariate values, we'll borrow info from multiple instruments and average to get something more precise

Estimation and Inference

• Our reweighting estimands other than CATE have the form,

$$\theta_{\mathrm{s}} = \mathbb{E}[\Delta^{z}(\mathrm{x})\omega_{\mathrm{s}}^{j}(\mathrm{x})], \ \omega_{\mathrm{s}}^{j}(x) = \mathbb{P}[\mathrm{s}^{j} = 1 \mid \mathrm{x} = x]/\mathbb{P}[\mathrm{s}^{j} = 1],$$

for $j \in \{z, w\}$

 Replace expectations 𝔼 and probabilities 𝒫 by empirical analogs, 𝔼_n and 𝒫_n:

$$\hat{\theta}_{\mathrm{S}} = \mathbb{E}_{n}[\hat{\Delta}^{z}(\mathrm{X}_{i})\hat{\omega}_{\mathrm{S}}^{j}(\mathrm{X}_{i})], \ \hat{\omega}_{\mathrm{S}}^{j}(x) = \mathbb{P}_{n}[\mathrm{S}_{i}^{j} = 1 \mid \mathrm{X} = x]/\mathbb{P}_{n}[\mathrm{S}_{i}^{j} = 1]$$

- Â^z(x) can be Wald with instrument z in cell x, or 2SLS (or GMM) using both z and w as instruments
- For LATE, S_i^j is not observable, so we use

$$\hat{\omega}_{\Delta}^{j}(x) = \frac{\mathbb{E}_{n}[D_{i} \mid J = 1, X = x] - \mathbb{E}_{n}[D_{i} \mid J = 0, X = x]}{\mathbb{E}_{n}[D_{i} \mid J = 1] - \mathbb{E}_{n}[D_{i} \mid J = 0]}, J \in \{Z, W\}$$

- Consistency of $\hat{ heta}_{
m s}$ follows from LLN and the Slutsky theorem

Inference under CEI

- Estimators are smooth functions of IV/GMM estimators and therefore asymptotically normal under standard regularity conditions
- Two routes to inference: delta method to derive the asymptotic variance, or resampling methods
- The bootstrap saves us from having to evaluate complicated analytical formulas
- Consistency of bootstrap for reweighting estimators follows from Hall and Horowitz (1996), Hahn (1996), Brown and Newey (2002) theorems for GMM, and delta method for bootstrap (see, e.g., Theorem 23.5 in van der Vaart, 1998)
- How to bootstrap in practice? We go with the empirical likelihood (EL) bootstrap as described in Brown and Newey (1992)
 - EL bootstrap works well for moment restriction models because it uses an efficient estimator of the DGP

But Weight . . . estimation and inference for CATE

- We want to condition on {x : Δ^z(x) = Δ^w(x)}, but in finite samples we never have Â^z(x) = Â^w(x)
- We can use covariate-specific overidentification tests to find compatible values of x
 - The cov-specific overid test, J(x), measures $\|\hat{\Delta}^{z}(x) \hat{\Delta}^{w}(x)\|$
 - So we weight cell estimates as follows

$$\hat{\Delta}_{c}^{z,w} = \mathbb{E}_{n}[\hat{\Delta}^{z,w}(\mathbf{x}_{i})\hat{\omega}_{c}(\mathbf{x}_{i})]; \ \hat{\omega}_{c}(x) \propto \exp\left[-\frac{J(x)}{a_{n}(x)}\right],$$

where $\hat{\Delta}^{z,w}(x)$ is a covariate-specific GMM estimator using z and w, and $a_n(x) \to \infty$ and $a_n(x) = o(n)$;

- $\hat{\Delta}_{c}^{z,w}$ is consistent for CATE because: (a) $plim\frac{J(x)}{a_{n}(x)} = \infty$ where CEI fails; (b) $plim\frac{J(x)}{a_{n}(x)} = 0$ otherwise
- We can view the weights as a moment selection device in the spirit of Andrews (1999)
- Data-driven selection of an estimator is problematic (like pre-testing); see, e.g., Leeb and Potscher (2009)

Estimates

- Our empirical work focuses on a 12-cell representation of second child age and mother's education
 - Three 2nd-born age groups: \leq 4, (4,8], and > 8 (all mothers 2+)
 - Four schooling groups: HS dropout, HS graduate, some college, and college graduate
- These covariates are strongly related to compliance probabilities
 - Multiple births have larger first-stage effects on women with a young second-born and for women with some college and college degrees
 - Sex-composition compliers are relatively unlikely to be college graduates and have older second-borns
- Labor supply effects are also likely to vary with these covariates
 - The birth of a third child has little effect on the work behavior of a woman with a young second-born if she is at home anyway
 - Relatively educated women with high wages should be affected less by the birth of a child than less-educated women

Estimates (cont.)

- Table 3 reports the conditional estimates $\hat{\Delta}^{z}(x)$ and $\hat{\Delta}^{z,w}(x)$, and the weighting functions $\hat{\omega}_{s}^{z}(x)$ and $\hat{\omega}_{CATE}^{z}(x)$ for each cell
 - Women with a third child differ from those without
 - As we saw in table 2, *Twins* and *samesex* compliers have different characteristics and differ from the random sample
 - The overid rejects CEI in only two cells for weeks worked (only one for employment), though covariate-specific IV estimates are fairly noisy
- Table 4 compares IV, GMM, and LATE-reweighted estimates
 - Reweighting covariate-specific *twins* estimates using *samesex* weights and vice versa brings the estimates together
 - ATE, TOT, and to a lesser extent TNT are poorly matched (twins LATE *is* TNT)
 - Downweighting a few bad cells, CATE matches well (compare -3.80 and -3.66 for weeks and -.099 and -.095 for employment)

The Compatible Subpopulation 👄

- For a given over-identified model, the CATE subpopulation potentially depends on the dependent variable
- **Figure 1** describes the compatible subpopulation for two versions of CATE, the first using weeks worked, the second using employment
- The two plots show $\hat{\omega}_{c}(x)$ and $\hat{\omega}_{c}(x) dF_{\mathrm{X}}(x)$
- Relative to the covariate histogram, CATE subpopulations emphasize:
 - Women with young second-borns
 - More educated mothers among those with older second-borns
- CATE weights are something like those for LATE(twins) and hence the population of non-treated
 - (not quite the same since TNT did not match all that well, but both emphasize women with younger second-borns and more educated)
- We knew that twins identify TNT, but this result shows samesex results appropriately reweighted are almost equally general

Summary and Directions for Further Work

- By assuming differences in complier characteristics are what make IV estimates special, we can construct estimates for new subpopulations from covariate-specific LATEs
- This works surprisingly well for the Angrist and Evans (1998) example: twins and samesex estimates are reconciled!
- When CEI fails for some cells, we use the traditional overid test statistic to find a population for which a given pair of IV estimates are compatible
- CATE achieves external validity by favoring cells with complier-independent effects (external validity is for these cells only: no free lunch)
- Implicit pretesting makes inference for compatible effects challenging
- The development of robust and convenient inference procedures for CATE is a natural direction for further work

Tables and Figures

Table 1: Wald estimates of the effects of family size on labor supply

Note: The table reports OLS, Wald, and 2SLS estimates of the effects of a third birth on labor supply using twins and sex composition instruments. Data are from the Angrist and Evans (1998) extract including women aged 21-35 with at least two children in the 1980 census. OLS models include controls for mother's age, age at first birth, ages of the first two children, and dummies for race. The first stage is the same for all dependent variables.

Table 2: Complier characteristics ratios for twins and sex composition instruments

Notes: The table reports an analysis of compiler characteristics for twins and sex composition instruments. The ratios in columns 3 and 5 give the relative likelihood that compilers have the characteristic indicated at left. The values in columns 2 and 4 in Panel B. represent Abadie's (2003) kappa-weighted means. Data are from the 1980 census 5 percent sample including mothers aged 21-35 with at least two children, as in Angrist and Evans (1998). The sample size is 394,840 for all columns.

Table 3: LATE decompositions (n = 394,840)

Notes: Standard errors for estimates in parentheses. J-weights are the exponential of minus the overidentification test statistic, normalized to have mean one. The p-value for the joint J-statistic for all the covariate values is 0.25 for weeks and 0.29 for LFP.

| | | | Weeks | worked | Emplo | yment |
|--------------|--------------------------|----------------------------|-----------------|--------------------|-------------------|--------------------|
| Effect | Conditional LATE Δ(X) | Weighting function ω(X) | Estimate [1] | t for diff [2] | Estimate [3] | t for diff [4] |
| LATE twins | twins | twins | -3.15 (0.62) | 1.32 | -0.075 (0.014) | 0.93 |
| | samesex | | -2.71 (0.81) | | -0.068 (0.018) | |
| LATE samesex | samesex | samesex | -6.30 (1.15) | 1.44 | -0.131 (0.026) | 0.77 |
| | twins | | -5.08 (1.58) | | -0.115 (0.037) | |
| ATE | twins | 1 | -2.84 (0.76) | 1.99 | -0.067 (0.017) | 1.58 |
| | samesex | | -5.88 (1.35) | | -0.123 (0.031) | |
| | twins, samesex | | -4.36 (0.60) | | -0.092 (0.014) | |

Notes: Standard errors for estimates in parentheses. T-statistics are for the difference between samesex and twins estimates. Standard errors and t-statistics obtained by Brown and Newey (2002) GMM bootstrap with 1,000 repetions. In brackets, we report standard errors and t-statistics obtained by nonparametric bootstrap with 1,000 repetitions.
